1 Abstract

2 Mixtures and pure stands of perennial ryegrass, tall fescue, white clover and red clover were grown in a
3 3-cut and a 5-cut system in southern Norway, at a low fertilization rate (100 kg N ha⁻¹ year⁻¹). The
4 nutritional quality (annual weighted averages) of the dried forage from the two first harvesting years
5 was analysed. There was no significant effect of species diversity on crude protein (CP) concentration. In
6 the 3-cut system we found a significant species diversity effect leading to 10% higher ADF (acid
7 detergent fibre) concentrations, 20-22% lower WSC (water soluble carbohydrate) concentrations and 4%
8 lower NE_L (net energy for lactation) concentrations in mixtures as compared to pure stands (averaged
9 across the two first years). In the 5-cut system similar effects were seen in the first year only. This
10 diversity effect was associated with a reduction in WSC and NE_L concentrations and an increase in ADF,
11 NDF and CP concentrations in the grass species, and not in red clover, when grown in mixtures. This is
12 thought to be a combined result of better N availability and more shading in mixtures. Species diversity
13 reduced the intra-annual variability in nutritional quality in both cutting systems.

1 Introduction

2 There are marked differences in the nutritional composition of grasses and legumes, with legumes
3 having a higher concentration of crude protein (CP) and a lower concentration of fibre than grasses (e.g.
4 Hatfield *et al.*, 2007). The digestibility of all forages is reduced as a consequence of reproductive
5 development due to an increase in the proportion of stems and lignified cellulose, accompanied with an
6 increase in fibre concentration and a decrease in CP and readily digestible carbohydrates. The rate of
7 decrease in digestibility with reproductive development tends to be lower in legumes than in grasses
8 (Moore and Jung, 2001). There are also differences among species of legumes and grasses, which are
9 partly a result of variations in growth habit and the allocation of resources between stem and leaf
10 tissues. The timing of reproductive development and stem elongation varies among and within species,
11 as does the tendency to produce stems during regrowth after defoliation. As a result of the strong effect
12 of heading, stem development, and the age of tissues (Duru, 2008), nutritional composition is highly
13 influenced by the defoliation regime, with earlier and more frequent defoliation resulting in forage of
14 higher digestibility (Gardarin *et al.*, 2014).

15 The inclusion of legumes in grassland swards has several advantages, such as providing N to the
16 grasses through symbiotic N fixation, contributing to the dry matter (DM) overyielding which is often
17 obtained in species mixtures, and increasing the voluntary intake of forage by livestock due to attributes
18 that increase the rate of passage through the rumen (reviewed by Lüscher *et al.*, 2014). Nutritional
19 quality is also more stable across harvests in grass-legume mixtures than in pure stands of grasses
20 (Sleugh *et al.*, 2000; Sanderson, 2010). This is partly because grasses are generally earlier in reproductive
21 development than legumes, resulting in the effects of reproductive development being distributed over
22 a larger time span and balanced by the presence of species at other developmental stages. The
23 nutritional quality of mixtures is largely determined by the dominant species in the mixture, and
24 therefore it may change as the species composition changes from year to year (Deak *et al.*, 2007;
25 Sturludottir *et al.*, 2013; Brink *et al.*, 2015). There are few reported examples of species diversity effects
26 independent of sampling effects occurring among the species in a sward. Species diversity may also
27 improve nutritional quality through the repression of weeds (Tracy *et al.*, 2004; Picasso *et al.*, 2008) if
28 these have lower nutritional value. There is limited information available on how the nutritional
29 composition of forage plants is affected by plant interactions through N fixation or competition for light,
30 water and nutrients. We conducted an experiment with a four-species mixture sown with variable

1 species proportions and cultivated at a low N-input level and in two different cutting systems. The
2 effects of species diversity and cutting frequency on DM yield and changes in botanical composition over
3 time in the same experiment were described by Ergon *et al.* (2016). Here, we analysed the effects of
4 species diversity on the swards' nutritional quality and intra-annual stability over the two first harvesting
5 years. We asked the following questions:

- 6 1) Are there species diversity effects on forage nutritional variables?
- 7 2) Are any such diversity effects affected by cutting frequency?
- 8 3) What effect does species diversity have on intra-annual stability of nutritional quality?

9

10 **Materials and methods**

11 **Field experiment**

12 A field experiment, described in detail in Ergon *et al.* (2016), was conducted at Ås, Norway. In brief,
13 pure stands and mixtures of perennial ryegrass (*Lolium perenne* L.), tall fescue (*Festuca arundinacea*
14 Schreb.), red clover (*Trifolium pratense* L.) and white clover (*T. repens* L.) were sown in 2010 in a split
15 plot design with cutting system (3 or 5 cuts per year) as main plots, and sward type as subplots. Fertilizer
16 was applied at a rate equal to 100 kg N ha⁻¹ year⁻¹. After each harvest in 2011 and 2012, the harvested
17 material within each plot was mixed, and a sample (approximately 1 kg) was taken from all plots of one
18 of the two seed-rate treatments (20 kg ha⁻¹) in the experiment. In order to study the effect of sward type
19 on nutritional variables of single species, samples sorted into species fractions were also taken at the
20 first and last harvest in the 3-cut system in 2012.

21 **Analysis of nutritional quality**

22 Samples were dried at 60 °C and cut into smaller pieces. Representative subsamples were milled in a
23 Cyclotec 1093 sample mill (Foss A/S, Hillerød, Denmark) with a 1 mm sieve, and scanned with an NIR
24 spectrophotometer (NIRSystems 6500, Silver Spring MD, USA). The content of crude protein (CP),
25 neutral detergent fibre (NDF), acid detergent fibre (ADF), non-fibre carbohydrates (NFC), water-soluble
26 carbohydrates (WSC), net energy for lactation (NE_L), digestible energy (DE) and metabolizable energy

1 (ME) were determined in approximately 20% of the samples by chemical analyses of CP, NDF, ADF, NFC
 2 and WSC and calculations based on these variables, at Dairy One Forage testing laboratory, Itacha, NY
 3 USA. Energy variables were estimated according to Weiss *et al.* (1992), Van Soest and Fox (1992), Weiss
 4 (1993) and Weiss (1995). NIR data analysis, including collection of spectra, selection of samples for
 5 chemical analysis, local calibration and prediction, was conducted using ISI software (NIRS2, ver. 4.00,
 6 Intrasoftware International, Silver Spring MD, USA). Calibration and validation statistics are shown in a
 7 supplementary file (Table S1) as Supporting Information in the online version of this paper.

8 **Statistical analysis**

9 For each of the nutritional components the weighted average concentration across harvests,

10
$$\sum_{i=1}^n (\text{concentration}_i \times \frac{\text{dry matter yield}_i}{\text{dry matter yield}_{\text{total}}}),$$

11 and the annual yield of the nutritional component,

12
$$\sum_{i=1}^n (\text{concentration}_i \times \text{dry matter yield}_i),$$

13 where i is the harvest number and n is the total number of harvests per year, were calculated for each
 14 plot and year. The average values for each year and treatment are shown in a supplementary file (Table
 15 S2) as Supporting Information. The effect of cutting system, the species identity effects β_{Species} , the
 16 species diversity effect δ and the contributions of the pairwise species interactions $\delta_{\text{Species 1*Species 2}}$ to δ ,
 17 were estimated using the diversity-interaction models developed by Kirwan *et al.* (2007; 2009). This was
 18 performed as in Ergon *et al.* (2016, Model 1), using weighted average concentrations and annual yield of
 19 nutritional components as Y . The estimated species and species interaction coefficients were used to
 20 estimate the effect of varying the species composition of the four species-seed mixture on NE_L yield,
 21 keeping the proportion of each species within the 0.1-0.7 range. The intra-annual stability of nutritional
 22 quality was assessed using a mixed models approach to estimate the variability of the responses across
 23 harvests within a year. This was also performed as described in Ergon *et al.* (2016, Model 2). All models
 24 were fitted using the GLM and MIXED procedures in SAS 9.2 (SAS Institute Inc., Cary, NC, USA).

25

1 Results

2 Species diversity effects on nutritional composition of harvested forage

3 There were typical differences between legume and grass pure stands with legumes having higher
4 concentrations of CP (163-2260 g (kg DM)⁻¹) and lower concentrations of NDF (342-438 g (kg DM)⁻¹) and
5 WSC (136-187 g (kg DM)⁻¹) than grasses (90-130 g (kg DM)⁻¹, 453-544 g (kg DM)⁻¹ and 232-282 g (kg DM)⁻¹,
6 respectively) (β coefficients in Table 1). The legume pure stands tended to have higher NE_L
7 concentrations (5.89-6.31 MJ (kg DM)⁻¹) than grass pure stands (5.53-6.11 MJ (kg DM)⁻¹).

8 There was a significant diversity effect on ADF, WSC, NFC and NE_L concentrations in both cutting systems
9 except in the 5-cut system in the second year (Table 1). There was also a significant diversity effect on
10 NDF concentration in the 5-cut system in the first year. The effect was positive for NDF and ADF, leading
11 to concentrations in the centroid mixture which was 7-10% higher than in the average pure stand (Table
12 2). For WSC, NFC and NE_L the diversity effect was negative, leading to a WSC concentration in a centroid
13 mixture which was 20-22% lower, a NFC concentration which was 7-9% lower, and a NE_L concentration
14 which was 4% lower than in the average pure stand. There was no significant species diversity effect on
15 the CP concentration (Table 1). The diversity effects were not always transgressive (that is, having a
16 higher value than the highest pure stand value) and it was therefore checked whether the observed
17 diversity effects could be due to changes in species composition relative to the sown proportions (a
18 sampling effect) by comparing the measured ADF, NDF, WSC, NCF and NE_L concentration with the
19 concentrations that would be expected based on observed, rather than sown, species proportions in the
20 mixtures (Table 3). The measured concentrations of ADF, NDF, WSC and NFC concentrations in both
21 cutting systems, and of NE_L concentration in the 3-cut system, were still different from what would have
22 been expected based on observed species proportions. This result indicated that the diversity effects on
23 these variables were due to one or more species having different quality in mixtures than in pure stands.
24 Analyses of nutritional quality in species-separated samples from the first and last harvests in the
25 second year in the 3-cut system showed that the grass species had higher concentrations of CP, ADF and
26 NDF, and lower concentrations of WSC, NFC and NE_L, when grown in mixtures compared with pure
27 stands (Table 4). In the last harvest the CP concentration in the grasses was 40-50% higher in mixtures
28 than in pure stands. ADF and NDF concentrations were 15-24 and 10-18% higher, and NE_L
29 concentrations 8-10% lower, when the grasses were grown in mixtures as compared to pure stands. In

1 the last harvest the two grass species differed in that the fibre and NE_L concentrations were not
2 significantly affected in perennial ryegrass while they were in tall fescue. The concentrations of easily
3 digestible carbohydrates (WSC, NFC) were much lower in mixtures than in pure stands for both grass
4 species. At the first harvest the concentration of WSC was 32-41% lower and at the last harvest it was
5 69-76% lower in mixtures than in pure stands. In red clover, the CP concentration was not affected by
6 stand type at all. For the carbohydrate fractions there was an opposite tendency to that seen in grasses,
7 and in the last harvest the WSC concentration was significantly higher in mixtures than in pure stands.
8 The results did not appear to be influenced by reproductive development, as tall fescue did not produce
9 flowering stems in the last harvest, while red clover produced a lot of flowering stems, and perennial
10 ryegrass a limited amount (data not shown). Sorted samples of white clover were not analysed due to
11 limited white clover biomass in the samples from these harvests.

12 **Species diversity effects on annual yields of crude protein and energy**

13 Due to the strong positive and transgressive diversity effect on DM yield (Table 2 and Ergon *et al.* 2016),
14 there were also significant positive and transgressive diversity effects on annual yields of nutritional
15 components in both cutting systems and both years. The predicted annual NE_L yield of a centroid
16 mixture was 52-72% higher than in the average pure stand (Table 2 and Supplementary File Table S3).
17 The annual yield of CP is of particular interest, as it provides information on the N status of the swards.
18 The predicted annual CP yield of a centroid mixture was 60-83% higher than in the average pure stand
19 and 7-27% higher than in the red clover pure stand, which was the species with the highest CP yield.
20 When we estimated the effect of varying the proportion of one species in the seed mixture from 0.1 to
21 0.7 while keeping the seed weight ratio between the three other species constant at 1:1:1 (Figure 1A),
22 the maximum accumulated NE_L yield over the two years was estimated when the red clover proportion
23 was 0.1 (both cutting systems). Together with the white clover this corresponds to a total legume
24 proportion of 0.4. When we manipulated the white clover proportion, the maximum accumulated yield
25 was obtained at a proportion of 0.1 in the 3-cut system and 0.4 in the 5-cut system, corresponding to a
26 total legume proportion of 0.4 and 0.6. For perennial ryegrass the optimal proportions were 0.5 and 0.3
27 in the 3 and 5-cut systems, respectively, while for tall fescue it was 0.3 and 0.4. This corresponds to total
28 legume proportions of 0.33 - 0.43. When we estimated the effect of varying the species seed weight
29 ratios in all combinations, but keeping the minimum proportion of each species at 0.1, we found the
30 maximum accumulated NE_L yield in the 3-cut system was obtained at proportions of 0.1 (red clover), 0.1

1 (white clover), 0.4 (tall fescue) and 0.4 (perennial ryegrass), while the maximum accumulated NE_L yield
2 in the 5-cut system was obtained at proportions of 0.1 (red clover), 0.3 (white clover), 0.3 (tall fescue)
3 and 0.3 (perennial ryegrass) (Figure 3B).

4 **Intra-annual stability of nutritional quality**

5 Mixtures had lower intra-annual variability than pure stands for NDF, ADF, WSC, NFC and all three
6 energy concentrations in both the two first years, and for CP in the second year only ($\chi^2_{,6df} = 29.4-62.3$, v
7 $P < 0.0001$) (Figure 2).

8

9 **Discussion**

10 Differences between the species in CP, NDF, ADF and WSC content agreed with expectations. We found
11 that there were significant species diversity effects on the nutritional composition of herbage from
12 mixtures in the two first years of the 3-cut system and in the first year of the 5-cut system. Mixtures had
13 lower WSC and NFC concentrations, higher ADF concentrations and slightly lower NE_L concentration
14 than expected from the nutritional composition of pure stands. The diversity effects on WSC and ADF
15 could not be explained by a change in species composition after sowing, indicating that changes in the
16 nutritional composition in one or more species were involved. This was supported by the analysis of
17 nutritional composition of single species sorted from the mixtures which were sampled from the first
18 and last harvests in the 3-cut system the second year. These analyses showed that the grass species had
19 higher concentrations of fibre and CP and lower concentrations of easily digestible carbohydrates and
20 NE_L in mixtures than in pure stands. This may be an effect of higher availability of N, increased standing
21 biomass, higher competition for light and lower leaf to stem ratios, in the mixtures as compared to the
22 average pure stands (see Ergon *et al.*, 2016). Similarly, Gierus *et al.* (2012) found that perennial ryegrass
23 had a higher NDF concentration and a lower NE_L concentration when grown together with lucerne than
24 when grown in pure stand, and this coincided with a higher DM yield of the mixture. A reduction in
25 concentrations of WSC, accompanied by an increase in concentrations of CP, was observed in perennial
26 ryegrasses in mixtures with white clover by Evans *et al.* (1996). The difference between mixtures and
27 pure stands was particularly pronounced during late summer, when clover growth was strongest. Evans
28 *et al.* proposed that when growth demand for fixed carbon exceeds supply, such as when plants are

1 shaded, WSC levels are reduced. Consequently, high summer yield of legumes in mixtures may result in
2 a reduction in WSC content of the companion grass due to shading. No fertilizer was applied in the
3 experiment reported by Evans *et al.*, and differences in N availability and growth may therefore also
4 have played a role. The lack of significant diversity effects on nutritional quality in the second year of the
5 5-cut system in our experiment may be related to the lower DM yield and less shading there. In addition,
6 unlike in 2012, the harvests in the 5-cut system in 2011 were very unequal, with the second and fourth
7 average mixture harvest comprising 32 and 37% of the annual harvest, respectively (data not shown).
8 This may have caused a stronger diversity effect on nutritional quality in the 5-cut system in 2011 than if
9 the harvests had been more evenly spaced.

10 Mixtures of grassland species have a higher light interception relative to pure stands (Spehn *et*
11 *al.*, 2005) and grass species have longer leaves and shoots and invest more in supporting tissues and
12 specific leaf area when grown in mixtures, particularly if legumes are present, indicating a role of N
13 nutrition (Gubsch *et al.*, 2011). It is also known that N fertilization changes the chemical composition of
14 plants; CP concentration increases and WSC concentration decreases while the effects on structural
15 carbohydrates vary (Peyraud and Astigarrage, 1998; Hoekstra *et al.*, 2007). To what extent N fertilization
16 has an effect on structural carbohydrates may depend on whether the plants are in a vegetative or
17 reproductive growth stage. Calvière and Duru (1999) found an increase in the stem proportion of spring
18 growth grass herbage with increasing N and P status. We found, however, that even in the absence of
19 reproductive stems in the third harvest, tall fescue had significantly more structural carbohydrates when
20 grown in mixtures than in pure stands with low N supply. We also observed that tall fescue grew longer
21 leaves than perennial ryegrass in mixtures in the 3-cut system, which may have been associated with a
22 higher proportion of ADF-rich supporting tissues in tall fescue. The negative effect of species diversity on
23 nutritional quality in the grass component was not seen in red clover; in fact, species diversity tended to
24 have the opposite effect. Unlike the other species, red clover may have experienced more competition
25 for light in the pure stands than in mixtures, as the seeding rate used is high for legumes, and individual
26 plants in pure stands can become very large. Higher levels of competition in pure stands may have
27 caused a higher stem to leaf ratio and lower WSC concentration than in red clover plants grown in
28 mixtures.

29 Sturludottir *et al.* (2014) studied mixtures of timothy, smooth meadow grass, white and red
30 clover in Nordic and Canadian conditions at low N fertilization levels (40-80 kg ha⁻¹) and 2 cuts per year.

1 They analysed results across six sites and found strong diversity effects on DM yield over three years,
2 but the diversity effect on nutritional quality was marginal. They did observe species interactions on
3 nutrient variables, but these were both positive and negative and tended to cancel each other out. In
4 contrast, we observed a net effect on several nutrient variables, which may be due to specific climatic or
5 management conditions. Moreover, different grass species may vary in their responses to competition
6 for light, their plasticity in stem to leaf ratios, and the differences in chemical composition between
7 stems and leaves.

8 The diversity effect on nutritional quality observed in this study is likely to be associated with
9 the low level of N-fertilization. Pure grass swards would normally receive higher levels of N fertilization
10 than applied here, and this may be expected to have a similar effect on nutritional quality as cultivation
11 in mixtures with legumes. However, although nutritional quality (in terms of the concentration of easily
12 digestible carbohydrates) was somewhat lower in mixtures than in pure stands, there was still a very
13 strong positive effect of diversity on NE_L and CP yield. This is mainly due to the strong positive diversity
14 effect on DM yield (Ergon *et al.*, 2016). In addition, grasses absorb soil N efficiently, which has been
15 shown to increase the symbiotic N acquisition of legumes (Nyfeler *et al.*, 2011). Estimations indicated
16 that optimum seed weight proportions for accumulated DM yield over three years in four-species seed
17 mixtures of red clover, white clover, perennial ryegrass and tall fescue was 0.1, 0.2, 0.4, 0.3 (3-cut
18 system) and 0.1, 0.3, 0.3, 0.3 (5-cut system) (Ergon *et al.*, 2016). Due to the effect of species diversity on
19 NE_L concentration, the optimum proportions regarding accumulated NE_L yield over the two first years,
20 studied here, shifted in favour of less white clover in the 3-cut system (0.1, 0.1, 0.4, 0.4). This likely
21 reflects the stronger species diversity effect on nutritional quality in the 3-cut system than in the 5-cut
22 system.

23 High intra-annual nutritional stability is often desired, especially in the context of practical
24 farming. We found that the intra-annual nutritional stability was significantly higher in the average
25 mixture than in the average pure stand in both cutting systems. This may partly be due to the fact that
26 the four species have different seasonal patterns of stem formation and reproductive development.
27 Previous research has shown that a combination of species in a mixture can result in a spread of
28 herbage maturity through the year. For example, results from a mixture of three species (lucerne plus
29 two grasses) grown in Argentina showed that although all three species were most mature in the

1 summer, the grasses increased in maturity index during the spring, and lucerne extended its maturity
2 through the autumn (Machado *et al.*, 2007).

3 In conclusion, in our 3-cut system with low N fertilization, we found a significant species
4 diversity effect on the chemical composition of forage harvested from mixed swards, leading to a 10%
5 increase in ADF concentration, a 20-22% reduction in WSC concentration and a 4 % reduction in NE_L
6 concentration averaged across the two first years. This diversity effect was at least partly due to reduced
7 concentrations of WSC and increased concentrations of ADF in the grass component of mixtures
8 compared with pure grass stands. An effect of species diversity in the 5-cut system was only found in the
9 first year. We have also demonstrated that species diversity strongly reduces the intra-annual variability
10 in nutritional quality at two different cutting frequencies.

4 **Supporting information**

5 The following additional supporting information may be found in the online version of this paper

6 **Table S1.** Calibration and validation statistics for the ability of near-infrared spectroscopy to predict the
7 nutritive attributes of the validation samples. CP, crude protein; NDF, neutral detergent fibre; ADF, acid
8 detergent fibre; NFC, non-fibre carbohydrates, WSC, water-soluble carbohydrates, NE_L, net energy for
9 lactation; DE, digestible energy; ME, metabolizable energy.

10

11 **Table S2.** A) Weighted annual concentrations (g (kg DM)⁻¹ or MJ (kg DM)⁻¹) and B) annual yields (t ha⁻¹ or
12 GJ ha⁻¹) of quality components measured in different sown stand types in the two first years after the
13 sowing year. Lp, *Lolium perenne*; Fa, *Festuca arundinacea*; Tr, *Trifolium repens*; Tp, *T. pratense*; _p, pure
14 stand; C, centroid (25 % seed weight of each species sown); _d, dominated (67 % of the indicated
15 species, 11 % of each of the three other species sown). CP, crude protein; NDF, neutral detergent fibre;
16 ADF, acid detergent fibre; WSC, water-soluble carbohydrates; NFC, non-fiber carbohydrates; NE_L, net
17 energy for lactation. The averages of two replicate blocks are given.

18

19 **Table S3.** Parameter estimates for species identity coefficients β (LP, *Lolium perenne*; FA, *Festuca*
20 *arundinacea*; TR, *Trifolium repens*; TP, *T. pratense*) and the species diversity coefficient δ , on the yield of
21 net energy for lactation (NE_L, GJ ha⁻¹) and crude protein (CP, t ha⁻¹) in mixtures of the four species. The
22 species identity coefficient equals the variable estimates in pure stands, while the species diversity
23 coefficient equals the variable estimate in a centroid mixture minus the average of pure stands. All
24 estimates were significant at $P < 0.0002$.

25

26

1 **Table 1.** Parameter estimates for species identity coefficients β (LP, *Lolium perenne*; FA, *Festuca*
2 *arundinacea*; TR, *Trifolium repens*; TP, *T. pratense*) and the species diversity coefficient δ , on nutritional
3 variables in mixtures of the four species. The species identity coefficients equals the variable estimates
4 in pure stands (g (kg DM)^{-1} or MJ (kg DM)^{-1}), while the species diversity coefficient equals the variable
5 estimate in a centroid mixture minus the average of pure stands. Estimates significant at $P < 0.05$ are
6 bolded. CP, crude protein; NDF, neutral detergent fibre; ADF, acid detergent fibre; WSC, water-soluble
7 carbohydrates; NFC, non-fiber carbohydrates; NE_L , net energy for lactation.

Table 3. Measured concentrations of nutritional components (g (kg DM)⁻¹ or MJ (kg DM)⁻¹) as compared to expected concentrations, based on concentrations in pure stands and either sown species proportions, or observed species proportions. Species proportions were visually observed for each plot before each harvest and an annual average weighted for DM yield was calculated. Averages across all mixture types and replicates (N=10). NDF, neutral detergent fibre; ADF, acid detergent fibre; WSC, water-soluble carbohydrates; NFC, non-fibre carbohydrates; NE_L, net energy for lactation. *, significantly different from the measured concentration (LSD, P<0.05).

¹White clover was not analysed due to limited biomass in the samples

²Samples from both replicate blocks and five mixtures with different relative sown species proportions were included, unless when there was not enough biomass of the species in the sample.

A

B

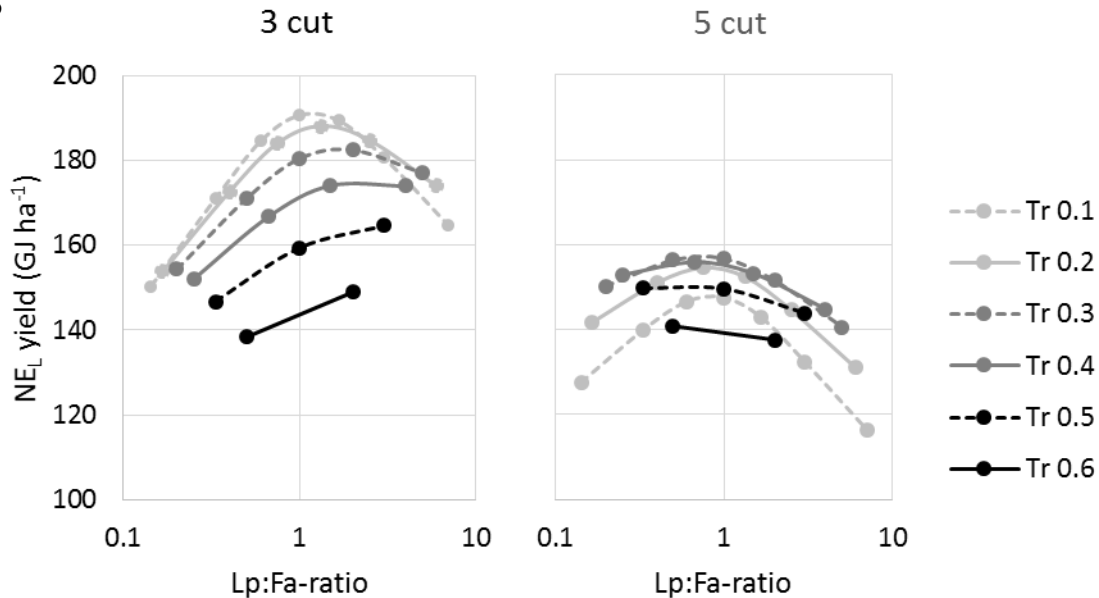

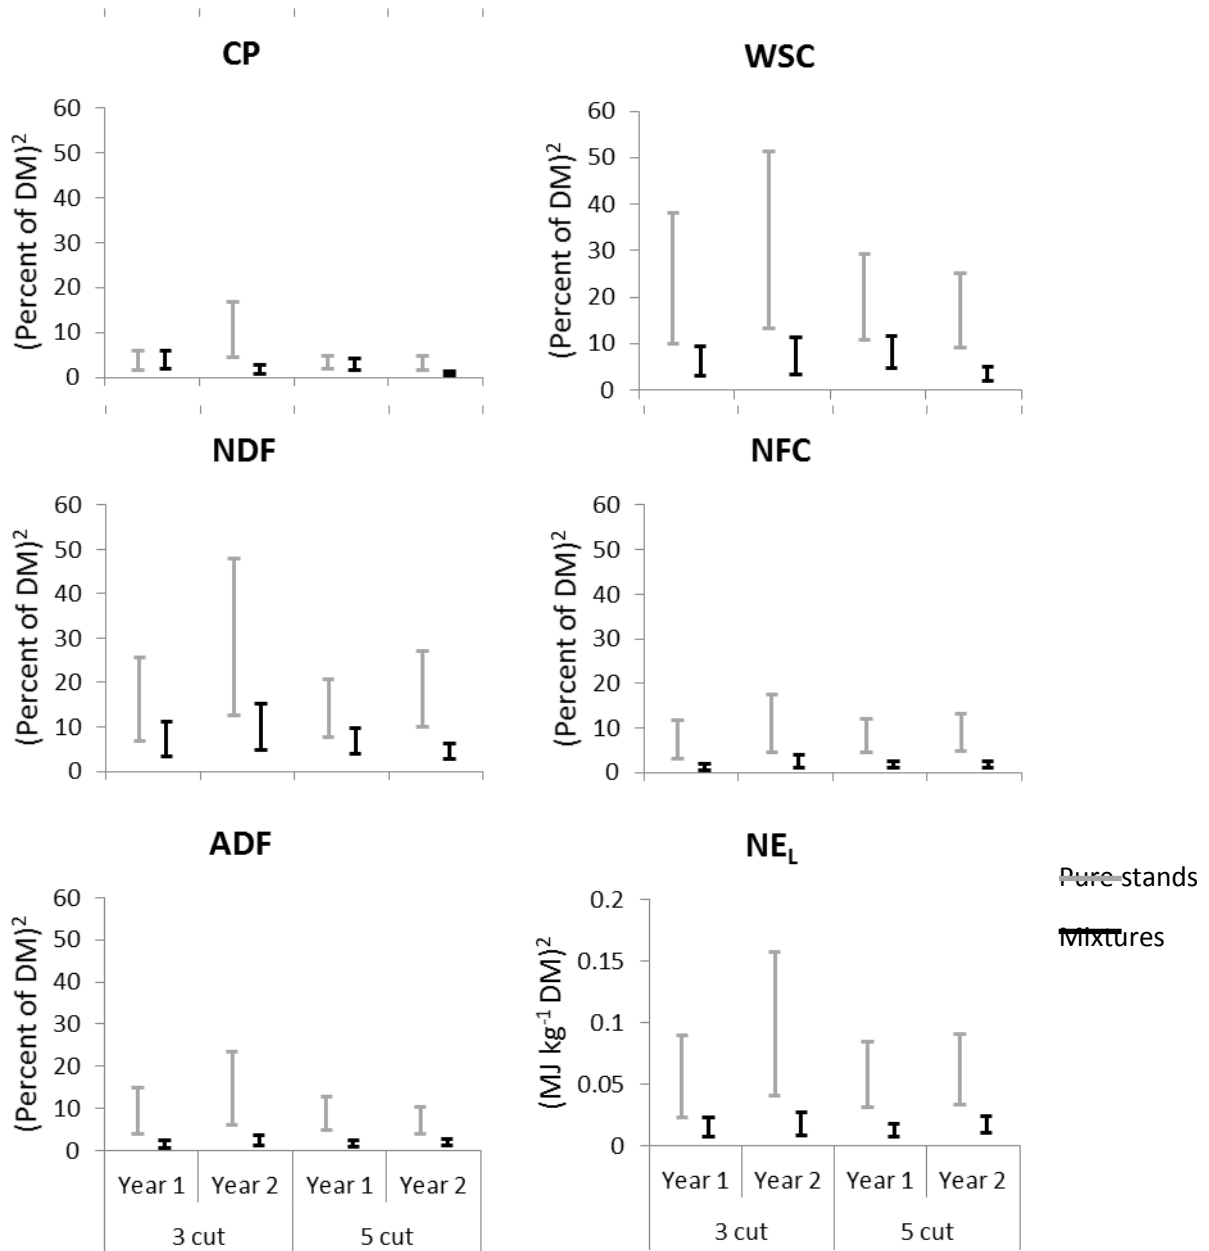

Figure 1. Estimation of total NE_L yield accumulated over the two first years in a 3 cut and a 5 cut system as a response to sown species composition (proportions of seed weight), using estimated species identity and species interaction coefficients for each species pair, cutting system and year. Lp, *Lolium perenne*; Fa, *Festuca arundinacea*; Tr, *Trifolium repens*; Tp, *T. pratense*. A) The proportion of the indicated species was varied from 0.1 to 0.7, keeping the ratios between the three other species constant at 1:1:1. B) The proportion of Tp was kept at 0.1 and the proportion of Tr was varied from 0.1 to 0.6. The ratio between Lp and Fa (x-axis, logarithmic scale) was varied within each level of Tr or Tp proportion.

1 **Table S3.** Parameter estimates for species identity coefficients β (LP, *Lolium perenne*; FA, *Festuca*
 2 *arundinacea*; TR, *Trifolium repens*; TP, *T. pratense*) and the species diversity coefficient δ , on the yield of
 3 net energy for lactation (NE_L, GJ ha⁻¹) and crude protein (CP, t ha⁻¹) in mixtures of the four species. The
 4 species identity coefficients equals the variable estimates in pure stands, while the species diversity
 5 coefficient equals the variable estimate in a centroid mixture minus the average of pure stands. All
 6 estimates were significant at $P < 0.0002$.
